HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L'archive ouverte pluridisciplinaire **HAL**, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d'enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.

AVERTISSEMENT

Ce document est le fruit d'un long travail approuvé par le jury de soutenance et mis à disposition de l'ensemble de la communauté universitaire élargie.

Il n'a pas été réévalué depuis la date de soutenance.

Il est soumis à la propriété intellectuelle de l'auteur. Ceci implique une obligation de citation et de référencement lors de l'utilisation de ce document.

D'autre part, toute contrefaçon, plagiat, reproduction illicite encourt une poursuite pénale.

Biopsie percutanée scano-guidée de lésion osseuse lytique chez des patients soupçonnés de cancer du poumon: performances diagnostiques pour analyse histologique et moléculaire

RÉSUMÉ :

Introduction: Les os sont un lieu fréquent de métastase du cancer pulmonaire. Les cliniciens sont souvent réticents à la biopsie des métastases osseuses, car elle nécessite un processus de décalcification qui endommage les acides nucléiques, la rendant incompatible aux tests moléculaires. Nous avons réalisé cette étude pour évaluer les performances diagnostiques histologiques et moléculaires des biopsies osseuses percutanées guidées par tomodensitométrie (TDM) des lésions osseuses lytiques lors de l'évaluation initiale ou de la progression du cancer du poumon.

Méthodes: Cette étude rétrospective a porté sur les patients chez lesquels un cancer primitif du poumon et des biopsies guidées par scanner d'os lytique ont été réalisées entre janvier 2010 et juin 2017. Le critère de jugement principal était la performance diagnostique histologique. Les critères d'évaluation secondaires étaient la performance diagnostique moléculaire et l'incidence des complications.

Résultats: Cinquante patients ont été inclus. Le rendement pour l'analyse histologique était de 100%, permettant dans tous les cas d'établir un diagnostic de certitude. Le pourcentage de cellules tumorales (mentionné dans 31/50 cas) était supérieur au seuil de 20% dans 83,9% des cas. Le rendement de l'analyse moléculaire était de 94,6% (35 échantillons sur 37). Une mutation a été trouvée dans 60% des cas; le plus souvent KRAS (28,6%) et EGFR (14,3%). Le taux de complications était de 2% : un pneumothorax mineur non drainé.

Conclusion: les biopsies d'os lytique percutanées scanoguidées sont associées à un taux de complications très faible et des performances diagnostiques histologiques et moléculaires élevées.

Abstract

Introduction:

Bone is a common location for lung cancer metastasis. Clinicians are often reluctant to biopsy bone metastases, as they are known to require a decalcification process that damages nucleic acids, which makes it incompatible with molecular testing. We performed this study to assess the diagnostic performance of histopathology and molecular testing of computed tomography (CT)-guided percutaneous bone biopsies of lytic bone lesions during the initial assessment or during the progression of lung cancer.

Methods:

This retrospective study included all patients suspected of having or known to have primary lung cancer and CT-guided percutaneous bone biopsies of lytic bone from January 2010 to June 2017. The main judgment criterion was the diagnostic performance of the pathological analysis. Secondary endpoints were the diagnostic performance of molecular testing and incidence of complications.

Results:

Fifty patients were included. The yield of CT-guided percutaneous bone biopsies for pathological analysis was 100%, allowing for a diagnosis of certainty in all cases. The percentage of tumor cells in samples (mentioned in 31/50 cases) was higher than the 20% threshold in 83.9% of cases. The yield of molecular analysis was 94.6% (35 of 37 samples). A mutation was found in 60% of cases; most frequently in *KRAS* (Kirsten rat sarcoma viral oncogene homolog) (28.6%) and *EGFR* (epidermal growth factor receptor) (14.3%). The complication rate was 2%, i.e. a minor undrained pneumothorax.

Conclusion: CT-guided percutaneous bone biopsies of lytic bone is associated with a very low complication rate and high diagnostic performance for histopathology and mutation testing.

Key words: lung cancer; bone metastasis; core biopsy; computed tomography; CT-guided biopsy; histopathology; molecular biology; tumor genotype.

Introduction

The management of advanced stage non-small cell lung cancer (NSCLC) has significantly improved in the last decades with the introduction of personalized treatments showing better efficacy than chemotherapy [1,2]. However, such treatments require precise histopathological subtyping of the tumor, molecular testing and PD-L1 (Programmed death-ligand 1) immunohistochemistry (IHC) to predict immune checkpoint inhibitor response. In cases of tumor progression, a rebiopsy is often performed with specific molecular testing to detect mechanisms of EGFR (epidermal growth factor receptor) or ALK (anaplastic lymphoma kinase) inhibitor resistance. Finally, this multistep approach for the biological diagnosis of lung cancer requires sufficient quantity and optimal quality of material [3]. Alternatively, while the number of biological tests has increased, sample size has decreased with the growing development of small biopsies under local anesthesia, such as those provided by computed tomography (CT)-guided biopsies.

The contribution to the histopathological diagnosis and molecular testing of CT-guided biopsies of NSCLC bone metastases (initial diagnosis or rebiopsy at progression) is, however, poorly understood. Indeed, whereas bone is a frequent or exclusive site of lung cancer metastasis, biopsies frequently require decalcification, with acidic reagents leading to degradation of nucleic acids and DNA, incompatible with molecular testing [4].

Nonetheless, it has been shown that biopsies of lytic bone lesions perform better, regarding diagnosis and theranostics, than biopsies of sclerotic bone lesions [5,6]. To our knowledge, no studies have specifically examined the performances and complications of CT-guided percutaneous bone biopsies in patients with suspected or known advanced lung cancer.

Complications of bone biopsies are on the order of 0.2 to 1.6% for percutaneous biopsies, compared to 6 to 16% for open surgical biopsies [7], including hematomas, pneumothorax and neurological complications. In a meta-analysis involving 9,500 patients,

Murphy [8] recorded severe neurological complications (paralysis, meningitis) in 0.08% of cases and death in 0.02%. The theoretical risk of dissemination on the path of biopsy is low.

The purpose of our study was to determine the diagnostic performance and complication rate of imaging-guided percutaneous needle core biopsy in patients with lytic bone metastases and known or suspected lung cancer.

Materials and Methods

Subjects and study design

This monocentric retrospective study was conducted at the University Hospital of Grenoble Alpes, France. All patients known or suspected of having lung cancer who received CT-guided percutaneous bone biopsies of a lytic bone between January 2010 and June 2017 were included. Lytic bone lesions were detected by regular contrast enhanced CT of the thorax, abdomen and pelvis and defined as a bone defect filled with tissue density material, with or without cortical rupture. Patients with lytic bone metastases of known extra-pulmonary origin were excluded as well as those with entirely sclerotic bone lesions. The main endpoint of this study was the diagnostic performance of the pathological analysis. Secondary endpoints were the diagnostic performance of molecular testing and incidence of complications.

According to the French regulations for retrospective non-interventional clinical research, written information was delivered to the last known postal address to all selected patients, with the possibility of sending back, within the specified time limits (1 month), their opposition to the anonymous collection of their data. This study was registered at www.ClinicalTrials.gov with the identifier NCT03386916.

Data

Data for each CT-guided percutaneous bone biopsies were collected from our hospital's computerized patient record and the radiology information system (RIS-PACS). The patients' electronic medical records were reviewed to obtain clinical history.

Collected data included characteristics of the patient, biopsied lesion (location, size), occurrence of a complication during and after the biopsy, histopathological and molecular biology results and the resulting therapeutic impact.

Biopsy procedure

Prior to each CT-guided percutaneous bone biopsy, the risks and benefits of percutaneous biopsies were discussed and written informed consent was obtained from each patient.

All CT-guided percutaneous bone biopsies were performed by a board-certified radiologist (with 3 to 27 years of experience) or by a radiology resident under direct senior radiologist supervision.

Coagulation screening was performed before all procedures (exclusion criteria were an international normalized ratio > 1.5 or a platelet count $< 50,000/L$). For all patients, the biopsy was performed percutaneously under CT scan guidance.

All patients underwent a CT of the chest-abdomen-pelvis prior to biopsy to confirm the site of biopsy and calculate the optimal trajectory of the needle. At the time of biopsy, selected images were obtained in the area of interest with 1 mm-thick contiguous CT sections. The procedure was performed with the patient in a prone, supine, or lateral position, depending on the location of the lesion (Figure 1). The position allowed the easiest access route to avoid neurovascular structures and viscera. All CT-guided percutaneous bone biopsies were performed using a local anesthetic (20 mL of 1% lidocaine). We used a coaxial biopsy system consisting of a 15- or 17-gauge (G) outer needle (Angiotech coaxial introducer needle; Medical Device Technologies Inc., Gainesville, FL, USA) and a 16- or 18-G core biopsy needle (Angiotech BioPince™ full core biopsy instrument), respectively, which allows for 13-mm or 23-mm or 33-mm long core tissue biopsies. The coaxial technique allows for acquisition of multiple samples using only one transgression through the skin. The number of samples depended on the will of the radiologist in charge of the patient according to the visual quality and quantity of the material obtained. After the biopsy, the patients were transferred to the chest unit for a 3-hour clinical follow-up. A chest radiograph was performed

3 hours after the procedure in cases of thoracic biopsy. Biopsies were immediately fixed in formalin and embedded in paraffin within 24 hours.

Histopathological and molecular biology analysis

As mentioned in our prescription form, pathologists received the information of a lytic bone lesion to preclude decalcification.

Hematoxylin–eosin–safran (HES) sections of formalin-fixed and paraffin-embedded TTNB were analyzed histologically. The lengths of biopsies and the average percentage of tumor cells present on the slides were recorded.

For nonsquamous NSCLC, samples were tested by pyrosequencing or NGS (next generation sequencing) for *EGFR*, *KRAS*, *BRAF* (BRAF proto oncogene), and *HER2* (human epidermal growth factor receptor 2), and screened for *ALK* and *ROS1* (ROS1 proto oncogene) rearrangement by IHC and by FISH (Fluorescence in situ hybridization) for *MET* amplification in cases of EGFR TKI (Tyrosine kinase inhibitor) resistance. Detection of *MET* (hepatocyte growth factor receptor) exon 14 mutation was performed when requested by the oncologist. PD-L1 IHC (using the 22C3 assay) was performed starting in May 2015 and only for requested patients.

Complications

Immediate complications were collected on the radiologist's report. The clinical files were reviewed for complications.

Complications were classified as minor or major according to the Society of Interventional Radiology (SIR) Guidelines [9]. Minor complications consisted of pneumothorax without need for intervention, ground glass opacity around the target diagnosed as pulmonary hemorrhage, and transient hemoptysis. Major complications

consisted of pneumothorax requiring intervention, hemothorax, air embolism, needle tract seeding, and death. Intervention was defined as treatment consequences (manual aspiration, chest tube placement, or pain control) or hospital admission.

Statistical analysis

The diagnostic performance of CT-guided percutaneous bone biopsies of lytic bone for histopathology was calculated by the number of samples that could be analyzed / total number of bone biopsies performed x100. The diagnostic performance of molecular analysis was calculated as the number of analyzable samples / total number of samples sent for molecular testing x 100.

Tumor size is the sum of the larger tumor axis and the larger perpendicular axis divided by two [10]. The percentage of tumor cells collected was classified according to the following threshold values: less than 20%, between 20 and 50% and greater than 50%, acknowledging that a minimum rate of 10 to 20% is commonly necessary for genetic testing.

Quantitative variables were expressed as median [interquartile (IQR) 25%-75%] and qualitative variables as n (%).

All statistical analyses were performed using SAS 9.4 (SAS Institute, Cary, NC, USA).

Results

Patients

A total of 773 biopsies were collected in the thoracic imaging unit of our hospital during the study period (Figure 2). Of these, 58 (8%) involved suspected bone metastases in patients with known or suspected primary lung cancer. Eight patients were excluded because the suspected bone lesions were not lytic. Finally, data from 50 patients with biopsies of lytic bone were included.

The main characteristics of biopsies are reported in Table 1. The characteristics of the biopsied lesions in terms of morphology and location are reported in Table 2. The average size of the biopsied lesions was 33 mm (IQR 25%-75%, 24-43 mm), located 27 mm deep (IQR 25%-75%, 20-36 mm). Bone lesions affecting the thoracic region (41 biopsies / 50, 82%) were at a median distance of 0 mm from the pleura (IQR 25%-75%, 0-6). Costal location predominated (28 cases (56%)), followed by sternum and iliac bone locations. A median of 3 biopsy samples were taken (1 to 5 samples, IQR 25%-75%, 2-3) with a median sampling length of 13 mm [IQR 25%-75%, 13-23]. A majority of biopsies were performed with a 16G needle (n=33, 66%).

Performance of histopathology and molecular analyses

The biopsy was informative in 100% of cases. Lung adenocarcinoma accounted for the majority of the cases (31 patients (62%)). Table 3 summarizes the main results.

For 31 (62%) patients, the percentage of tumor cells was mentioned in the pathological report. Among them, 26/31 (84%) patients had a tissue sample with more than 20% tumor cells and higher than 50% in 58.1%, allowing for reliable molecular analysis.

Molecular testing was requested for 37 of the 50 patients (74%), consistent with the current recommendations according to histological subtype of the tumor (Table 3). In 35/37 cases, the molecular analyses could be performed. Two samples were not analyzable due to

insufficient tissue material. In 21 patients, mutations were identified, mainly *KRAS* mutations (n=10; 29%) and *EGFR* mutations (n=6; 17%). In one patient, an adenocarcinoma was diagnosed on a biopsy performed during fibroscopy, but due to insufficient material for molecular testing, a biopsy of the metastatic bone was subsequently performed and showed an *EGFR* mutation.

Complications

Only one (2%) complication was detected. The complication was a pneumothorax of low abundance (13 mm thick) complicating a biopsy of a rib and requiring no drainage or specific management and therefore was minor according to the SIR classification.

Therapeutic Impact

Following the bone biopsy analyses, 8 patients received a specific targeted therapy, 28 received chemotherapy and 3 received immunotherapy. No follow-up information was found for 1 patient.

In 8 patients, an *EGFR* mutation or *ALK* translocation was identified. Six received a new targeted therapy. For the other 2 patients, no new targeted therapy could be proposed, and the patients received chemotherapy.

Discussion

Our retrospective study showed a 100% yield for histopathological diagnosis. Forty-five biopsies (90%) showed metastases from a primary lung cancer, of which adenocarcinoma was the most common subtype (62%). The diagnostic yield for molecular biology was 94.6% (35/37). A mutation was found in 60% of cases, and the most frequent were in *KRAS* (28.6%) and *EGFR* exons 19-21 (14.3%), in accordance with the literature [11]. The percentage of tumor cells in samples (mentioned in 31/50 cases) was higher than the usually recommended 20% threshold [12] in 83.9% of cases. The complication rate was very low (2%), in the form of a minor complication with spontaneous resolution of the pneumothorax type.

One of the criteria for inclusion in our study was the osteolytic nature of bone lesions on CT images, i.e., the calcified bone structure was replaced by soft attenuation tissue, with or without rupture of the cortical bone. This presentation at CT allowed for the following:

1/ Using a simple coaxial technique protocol of biopsy without specific tools that are required to biopsy suspected osteoblastic metastasis on the bone.

2/ Using a selected needle-length of the sample (13, 23, 33 mm) adapted to the size of the target lesion. As bone biopsies are at lower risk for complications than intrathoracic biopsies [8-10], we used larger diameter needles (16G) to optimize the quantity and quality of tissue samples. In our study, 66% of the samples (33 biopsies) were obtained with 16G needles and 34% (17 biopsies) with 18G needles.

3/ Specifying to the pathologist that the sample should not be decalcified before analysis. The absence of decalcification and subsequent absence of degradation of nucleic acids and antigens explains the excellent yield of histopathological and molecular analyses [3].

Indeed, the histopathological yield of bone biopsies in the literature varies according to the series, depending on the osteoblastic or osteolytic nature of the targeted lesion. The yield of histopathology in cases of lytic lesions biopsies was 71% in the study by Jelinek et al. [13]

(bone tumors) and 85% in the study by Fraser-Hill et al. [14]. For osteoblastic lesions, the yield varies between 69 and 82% [14, 15]. The study by Vieillard et al. [6] evaluated the yield of percutaneous bone biopsies for vertebral and peripheral bone tumors. The efficacy was higher for lytic lesions (87%; 64/73) than for osteoblastic lesions (66%; 2/3) but with no significant difference between these subgroups due to small figures. The lower diagnostic yield of osteoblastic lesions is due to the difficulty in identifying the tiny spinal cord areas within bone fragments containing a few groups of neoplastic cells [6].

When the amount of calcified bone tissue is small, it is not necessary to perform a decalcification step, which deteriorates membrane antigens and nucleic acids [16]. The study by VanderLaan et al. [5] evaluated the success rate of *EGFR/KRAS* mutations and *ALK* rearrangements by comparing surgical specimens of all types (pulmonary / lymph node / bone / pleural and cerebral) vs. percutaneous biopsy vs. bronchoalveolar lavage in non-small cell lung cancers. Failure rates for *EGFR* molecular testing were higher in percutaneous biopsy if the biopsy sample was bone: 40% (4/10) compared to 0% (0/13) ($p=0.024$) in surgical resection. Bone samples were of all types, lytic and condensing, with decalcification of tumor tissue before sample preparation correlating with a higher failure rate for genotypic research: 60% (3/5) vs. 5.5% (1/18) ($p=0.021$) for *EGFR* with similar rates for *ALK* (44% vs. 0%) and *KRAS* (22% vs. 0%).

Due to the infrequent availability of PET-CTs in our PACS system at the time of bone biopsy, it was not possible to assess the correlation between the lytic nature of a bone lesion at CT chosen as a target and the hypermetabolic activity at PET-CT. This correlation was performed by Wei Guo et al. [17] in 51 patients with a strong suspicion of metastatic lung cancer and bone lesions. Biopsies confirmed the metastatic nature of bone lesions in 96.1% of cases (49/51 patients) after the first biopsy while a second sampling was needed in two patients. Forty-seven out of 51 lesions showed lung cancer metastases. *EGFR* molecular testing was

performed in 23 cases, 7 of which were positive (31.4%). *ALK* rearrangements tested positive in 31.6% of cases (6/19 patients). The results of the study by Wei Guo et al. [17] are comparable to those of the present study regarding the pathological efficiency of biopsies. We therefore question the interest of PET-CT to target the bone lesion in a lung cancer context, regarding its cost and low availability [18].

In the context of recent diagnosis or progression of lung cancer with secondary bone metastases, the question of the choice of the lesion to biopsy, either the primary lung tumor or a secondary lytic bone lesion, arises. For many clinicians, a biopsy of a bone lesion is not desirable because of the decalcification process that degrades the quality of the samples [16]. The study by Ferretti et al. performed in 2013 [19] included CT-guided lung biopsies. Confirmation of lung cancer was obtained in 80 to 95% of cases, with successful molecular biology tests in nearly 95% of cases for *EGFR* and *KRAS* and 100% for *ALK*. The cancer cell count on the samples was approximately 42%. The results of the present study are similar and demonstrate the importance of osteolytic bone sampling in the specific context of bronchopulmonary cancers.

The benefit/risk ratio is an important issue for the choice of any invasive procedure. All of the published studies in the literature on percutaneous bone biopsies show extremely low complication rates [6, 13, 18, 19-22], including Lorenzo Monfardini's retrospective study [23], which included 308 percutaneous bone metastases and reported complications in 3.5% (11/308), all considered minor. This result is consistent with our study, which found only one minor complication (2%), a limited pneumothorax. In contrast, CT-guided lung biopsies have a substantially higher complication rate as recently confirmed in the multicenter retrospective analysis by Fontaine-Delaruelle et al. [24], who showed complications in 34% of cases (pneumothorax and hemoptysis), including 6% that were severe complications (drained pneumothorax, hemoptysis or hemothorax).

Conclusion

CT-guided biopsy of lytic bone lesions occurring in a context of diagnosis or progression of lung cancer is a simple, safe and cost-effective procedure for pathological diagnosis and molecular biology analysis. The excellent yield of lytic bone biopsies associated with a low complication rate should encourage biopsies of lytic bone lesions if present and accessible instead of lung targets. In addition, these biopsies can be performed with the same material as soft tissue biopsies.

SERMENT D'HIPPOCRATE

En présence des Maîtres de cette Faculté, de mes chers condisciples et devant l'effigie d'HIPPOCRATE,

Je promets et je jure d'être fidèle aux lois de l'honneur et de la probité dans l'exercice de la Médecine.

Je donnerai mes soins gratuitement à l'indigent et n'exigerai jamais un salaire au dessus de mon travail. Je ne participerai à aucun partage clandestin d'honoraires.

Admis dans l'intimité des maisons, mes yeux n'y verront pas ce qui s'y passe ; ma langue taira les secrets qui me seront confiés et mon état ne servira pas à corrompre les mœurs, ni à favoriser le crime.

Je ne permettrai pas que des considérations de religion, de nation, de race, de parti ou de classe sociale viennent s'interposer entre mon devoir et mon patient.

Je garderai le respect absolu de la vie humaine.

Même sous la menace, je n'admettrai pas de faire usage de mes connaissances médicales contre les lois de l'humanité.

Respectueux et reconnaissant envers mes Maîtres, je rendrai à leurs enfants l'instruction que j'ai reçue de leurs pères.

Que les hommes m'accordent leur estime si je suis fidèle à mes promesses.

Que je sois couvert d'opprobre et méprisé de mes confrères si j'y manque.

THÈSE SOUTENUE PAR : Stéphane ASFARI

TITRE :

**PERCUTANEOUS CT-GUIDED BIOPSY OF LYTIC BONE LESIONS IN PATIENTS
CLINICALLY SUSPECTED OF LUNG CANCER: DIAGNOSTIC PERFORMANCES FOR
PATHOLOGICAL DIAGNOSIS AND MOLECULAR TESTING**

CONCLUSION :

CT-guided biopsy of lytic bone lesions occurring in a context of diagnosis or progression of lung cancer is a simple, safe and cost-effective procedure for pathological diagnosis and molecular biology analysis. The excellent yield of lytic bone biopsies associated with a low complication rate should encourage biopsies of lytic bone lesions if present and accessible instead of lung targets. In addition, these biopsies can be performed with the same material as soft tissue biopsies.
